ABSTRACT
OBJECTIVE: The aim of this study was to systematically review dextrose (α-glucose) prolotherapy efficacy in the treatment of chronic musculoskeletal pain.
DATA SOURCES: Electronic databases PubMed, Healthline, OmniMedicalSearch, Medscape, and EMBASE were searched from 1990 to January 2016.
STUDY SELECTION: Prospectively designed studies that used dextrose as the sole active prolotherapy constituent were selected.
DATA EXTRACTION: Two independent reviewers rated studies for quality of evidence using the Physiotherapy Evidence Database assessment scale for randomized controlled trials (RCTs) and the Downs and Black evaluation tool for non-RCTs, for level of evidence using a modified Sackett scale, and for clinically relevant pain score difference using minimal clinically important change criteria. Study population, methods, and results data were extracted and tabulated.
DATA SYNTHESIS: Fourteen RCTs, 1 case–control study, and 18 case series studies met the inclusion criteria and were evaluated. Pain conditions were clustered into tendinopathies, osteoarthritis (OA), spinal/pelvic, and myofascial pain. The RCTs were high-quality Level 1 evidence (Physiotherapy Evidence Database ≥8) and found dextrose injection superior to controls in Osgood–Schlatter disease, lateral epicondylitis of the elbow, traumatic rotator cuff injury, knee OA, finger OA, and myofascial pain; in biomechanical but not subjective measures in temporal mandibular joint; and comparable in a short-term RCT but superior in a long-term RCT in low back pain. Many observational studies were of high quality and reported consistent positive evidence in multiple studies of tendinopathies, knee OA, sacroiliac pain, and iliac crest pain that received RCT confirmation in separate studies. Eighteen studies combined patient self-rating (subjective) with psychometric, imaging, and/or biomechanical (objective) outcome measurement and found both positive subjective and objective outcomes in 16 studies and positive objective but not subjective outcomes in two studies. All 15 studies solely using subjective or psychometric measures reported positive findings.
CONCLUSION: Use of dextrose prolotherapy is supported for treatment of tendinopathies, knee and finger joint OA, and spinal/pelvic pain due to ligament dysfunction. Efficacy in acute pain, as first-line therapy, and in myofascial pain cannot be determined from the literature.
KEYWORDS: dextrose, prolotherapy, musculoskeletal pain, evidence-based medicine, systematic review, osteoarthritis chronic pain

Background
The Institute of Medicine defines chronic pain as pain that persists for a period of three to six months or beyond the time of normal healing.¹ Musculoskeletal disorders are the most common source of chronic pain experienced by American adults.² In 2012, the National Health Interview Survey indicated that half of all adults (aged 18 years and over) reported suffering from a musculoskeletal condition lasting three months or longer, with higher prevalence in women and those in lower income groups.³ In the United States, musculoskeletal conditions are the single most common reason for patients visiting their physicians (Fig. 1). According to the data collected by the Centers for Disease Control and Prevention 2010 National Ambulatory Medical Care Survey, over 97 million American adults visited a physician for musculoskeletal-related complaints or symptoms during that year.⁴ Of all the musculoskeletal complaints, cervical and lumbar back pains are the most common symptoms for which adult patients seek medical intervention.⁵ Of these, one in four individuals is 65 years or older. In 2012, between 12% and 14% of the United States population visited primary care physicians with complaints of back pain. Data indicate that the number of physician visits for pain is increasing. In 2012, more than 52.3 million patients visited a physician with symptoms of back pain, compared to 44.6 million in 2004.⁴,⁵ No estimation has been made of the great number of those who seek chiropractic care or physical therapy for treatment of back pain.
Joints of the upper and lower extremities are other common sites of musculoskeletal pain. Between 2002 and 2009, almost 30% of American adults reported recent symptoms of pain, aching, or swelling around a joint. The second and third most common sites for chronic musculoskeletal pain reported by adults are knee joints and shoulder joints, which affect 40 million and 19 million people, respectively. One in four adults aged 18–64 years report chronic joint pain from multiple joints, and among those 65 years and older, the ratio jumps to more than two in five.

Not only are musculoskeletal conditions the most common cause of chronic pain, but they also result in significant disability in one out of every two individuals affected. In the United States, 55% of adults with joint pain have difficulty with basic activities, such as movement and sensory, emotional, and mental functioning, or have limitations in complex activities that include full participation in social, occupational, and household functioning. In 2014, nearly 18 million adults reported that they were unable to perform at least one daily activity, such as self-care, walking, and rising from a chair due to their musculoskeletal conditions. The disabling nature of chronic pain stemming from musculoskeletal conditions can result in isolation, disruption of social activities and relationship involvement, financial hardship, lost productivity, and potential unemployment.

The economic impact of musculoskeletal conditions in the United States is staggering. In 2011, they cost $796.3 billion, nearly 6% of the annual GDP. According to the Institute of Medicine and the United States Bureau of Labor, nearly one million people take time away from work every year to treat and recover from pain or loss of function due to musculoskeletal conditions in the low back or upper extremities. In 2012, one in eight adults of prime working age reported lost work days due to a musculoskeletal condition – totaling 216 million days. Such injuries are often more severe than the average nonfatal workplace injury or illness and require longer recovery time, entailing an average of nine recovery days compared to an average seven days for all other workplace injuries.

The predictable aging of the baby boomer cohort is projected to intensify the burden of musculoskeletal disease and disorders. Currently, these disorders account for more than 50% of all chronic conditions in people older than 50 years and are the most common cause of severe, long-term pain and disability in those aged over 65 years. The rising obesity epidemic also adds to the burden, and there is a significant positive association between musculoskeletal disorders and obesity. Increased body mass index puts a substantial stress and strain on weight-bearing joints, especially the lower back, hips, and knees, increasing the severity of musculoskeletal disorders. According to the Centers for Disease Control, obese adults receive a diagnosis of arthritis twice as often as nonobese individuals. Obese individuals are also particularly at high risk for injuries to upper extremity joints, due to biomechanical compromises linked with higher body weight.

The increasing prevalence and burden of musculoskeletal conditions has led to an interest in effective nonsurgical solutions, which are more cost efficient and do not have the risks or require the recovery time of surgical approaches. Prolotherapy is one such viable solution.

Prolotherapy. Prolotherapy has been used in clinical practice for more than 80 years to treat various chronic musculoskeletal conditions. Formalized by Dr. George Hackett in the 1950s, prolotherapy is a practical and efficacious therapeutic strategy to treat ligamentous laxity and related musculoskeletal and arthritic conditions. Interest in prolotherapy has intensified over the past two decades among both physicians and patients, accompanied by an increasing
number of published treatment outcome studies that confirm anecdotal findings that prolotherapy is effective in treating many conditions with few adverse effects, including osteoarthritis (OA),\textsuperscript{13} musculoskeletal pain,\textsuperscript{16} joint pain and laxity,\textsuperscript{16} chronic low back pain,\textsuperscript{17,18} refractory lateral epicondylitis,\textsuperscript{19} painful overuse tendinopathy, refractory,\textsuperscript{16} disabling low back pain,\textsuperscript{16} and refractory tendinopathies, and OA.\textsuperscript{20}

Prolotherapy is a nonsurgical regenerative injection technique that introduces small amounts of an irritant solution to the site of painful and degenerated tendon insertions (entheses), joints, ligaments, and in adjacent joint spaces during several treatment sessions to promote growth of normal cells and tissues.\textsuperscript{21–23} Irritant solutions most often contain dextrose (\(\beta\)-glucose), a natural form of glucose normally found in the body, but may also contain combinations of polidocanol, manganese, zinc, human growth hormone, pumice, ozone, glyc erin, or phenol.\textsuperscript{14} In severe cases, autologous cellular solutions may also be needed, such as platelet-rich plasma (PRP), bone marrow, or adipose tissue.\textsuperscript{24} A major goal of prolotherapy in chronic musculoskeletal conditions is the stimulation of regenerative processes in the joint that will facilitate the restoration of joint stability by augmenting the tensile strength of joint stabilizing structures, such as ligaments, tendons, joint capsules, menisci, and lабral tissue.\textsuperscript{25}

The most common prolotherapy agent used in clinical practice is dextrose, with concentrations ranging from 12.5% to 25%.\textsuperscript{20} Dextrose is considered to be an ideal proliferant because it is water soluble, a normal constituent of blood chemistry, and can be injected safely into multiple areas and in large quantity. Hypertonic dextrose solutions act by dehydrating cells at the injection site, leading to local tissue trauma, which in turn attracts granulocytes and macrophages and promotes healing. Dextrose prolifer ant has been approved for injection by United States Food and Drug Administration but not for prolotherapy; thus, it is currently used in prolotherapy as an off-label substance. The mechanism of action behind prolotherapy is not completely understood. However, current theory holds that the injected proliferant mimics the natural healing process of the body by initiating a local inflammatory cascade, which triggers the release of growth factors and collagen deposition. This is accomplished when induced cytokines mediate chemomodulation, which leads to proliferation and strengthening of new connective tissue, joint stability, and a reduction in pain and dysfunction.\textsuperscript{21,23,25} Figure 2 is a schematic depiction of the application of the therapeutic principle of prolotherapy – encompassing the inflammatory, proliferation, and tissue remodeling phases of the healing and restoration processes of injured ligaments/tendons.

\textit{In vitro} studies on human fibroblasts and chondrocytes exposure to extracellular dextrose concentrations of only 0.5% have resulted in the proliferation and production of a number of growth factors, several of which are essential to the repair, structural and functional integrity, and growth of tendons, ligaments, and other soft tissues.\textsuperscript{26–27} These include platelet-derived growth factor,\textsuperscript{38–39} transforming growth factor \(\beta\),\textsuperscript{40} epidermal growth factor,\textsuperscript{41} basic fibroblast growth factor,\textsuperscript{42} insulin-like growth factor,\textsuperscript{43} and connective tissue growth factor.\textsuperscript{27} \textit{In vitro} growth factors have been found to promote the expression of types 1 and 3 collagen in tenocytes and are pertinent to the growth of tendon, ligament, and cartilage.\textsuperscript{32–35}

Stimulation of the production of these key growth factors for ligaments, tendons, and cartilage through dextrose prolotherapy could be an inexpensive method of growth stimulation that may prove to be cost effective for the long term.\textsuperscript{35} When injected into tissue, exogenous dextrose has been found in animal and human studies to stimulate inflammatory response,\textsuperscript{36} ligament size,\textsuperscript{37} tendon hypertrophy,\textsuperscript{38–40} extracellular matrix,\textsuperscript{39–41} fibroblastic proliferation,\textsuperscript{39–42} and repair of articular cartilage defects.\textsuperscript{42,43} When used clinically, dextrose concentrations higher than 10% operate in part through inflammatory mechanisms, while concentrations less than 10% are considered noninflammatory.\textsuperscript{44}

\textbf{Methods}

\textbf{Objective.} The objective of this systematic review is to determine the efficacy of dextrose prolotherapy in chronic musculoskeletal pain.

\textbf{Search strategy and selection criteria.} A systematic review of English and non-English literature published from 1990 to January 2016 was performed using the PubMed, OmniMedicalSearch, Healthline, Medscape, Medline, and EMBASE databases. Keywords included prolotherapy, dextrose, regenerative injection therapy, and musculoskeletal pain. Medical Subject Headings (MeSH) terms included glucose/therapeutic use, intraarticular injections, glucose/administration and dosage, and sclerotherapy. Inclusion criteria were the involvement of human subjects, publication in a peer-reviewed journal, prospective study design, and use of dextrose as the sole prolotherapy proliferant. Exclusion criteria included use of prolotherapy solutions containing P2G, pumice, PRP, bone marrow, liposapire, stem cells, or sodium morrhuate\textsuperscript{e}; retrospective study design; or high velocity manipulation as adjunctive therapy. No lower limit was placed on sample size due to the small overall number of published trials. Non-English studies were considered if they met inclusion criteria, provided an abstract in English, and presented sufficient tabular/graphic data for data abstraction.

\textbf{Rating the quality of evidence.} The selection of instruments to assess the quality of evidence was influenced by the systematic reviews performed by Teasell et al.\textsuperscript{45} and Krassioukov et al.\textsuperscript{46}, where both controlled and uncontrolled studies were evaluated.

\textsuperscript{a}A study utilizing a proliferate of sodium morrhuate combined with dextrose for the treatment of lateral epicondylitis of the elbow was included; however, studies where sodium morrhuate was the only proliferant used were excluded.\textsuperscript{37}
The methodological quality of each study was scored with use of the Physiotherapy Evidence Database (PEDro) tool for randomized controlled trials (RCTs) and the Downs and Black (D&B) evaluation tool for non-RCTs. The PEDro is an 11-item scale that measures external validity (question 1) and internal validity (questions 2–11). The maximum score is 11; higher scores indicate better methodological quality, with 9–11 excellent, 6–8 good, 4–5 fair, and poor. The D&B tool contains 27 items that assess reporting, external validity, internal validity (bias), and internal validity (confounding) and has a maximum score of 28. In an evaluation of 194 different instruments, the D&B tool was among six tools identified as most suitable for use in systematic reviews for assessing methodological quality in nonrandomized studies; a further comparison of 18 tools identified the D&B as possessing the best reliability and validity to evaluate the quality of nonrandomized trials. For this review, PEDro and D&B scores were obtained by two independent reviewers. Heterogeneity and interrater agreement between reviewers in quality scoring was not formally assessed. The level of evidence of each study was determined with a modification of Sackett’s description of levels of evidence as described in Krassioukov et al.

Efficacy studies of pain therapy typically assess change in pain intensity from baseline with patient-reported ratings, usually with the visual analog scale (VAS) or numerical rating scale (NRS). Changes in pain score sufficient for clinical relevance can be determined by applying the minimal clinically important change (MCID) criteria. Developmental, quantification, and validation studies found that a reduction of three points represents the MCID using VAS, a reduction of two points represents the MCID using NRS and a decrease of 1.5 points with VAS and NRS represents a clinically irrelevant change in pain self-rating. Studies using VAS or NRS as outcome measurement were dichotomously rated as either MCID or NOT MCID. Study heterogeneity and limited RCTs in each pain subcategory prevented the aggregation of statistical data necessary to perform a meta-analysis. Studies assessing efficacy of dextrose prolotherapy for treatment of OA used the Western Ontario McMaster University Osteoarthritis Index (WOMAC; 100-point scale), which measures pain, stiffness, and functional movement.

Although the number of published studies on prolotherapy using RCT design demonstrating high levels of evidence are becoming more common, most published research on prolotherapy induces the three stages of healing and restoration: inflammation, proliferation, and tissue remodeling. Reused from: Steilen D, Hauser R, Woldin B, Sawyer S. Chronic Neck Pain: Making the Connection Between Capsular Ligament Laxity and Cervical Instability. The Open Orthopaedics Journal. 2014;8:326–345, under the terms of a CC-BY 2.5 license.
Dextrose prolotherapy has been nonrandomized prospective controlled trials, cohort studies, case–control series, case series, or single-subject case reports. Systematic reviews have largely been condition specific or have compared different types of injection therapies within the prolotherapy milieu. Furthermore, with the exception of one review by Sanderson and Bryant, which is limited to dextrose prolotherapy for the management of lower limb tendinopathy and fasciopathy, no recent systematic review has been published that solely addresses the efficacy of dextrose prolotherapy for multiple areas of chronic musculoskeletal pain and includes findings provided not only from RCTs but also those stemming from less rigorous research designs. Although designated lower levels of evidence, the studies discussed here, in addition to those using RCT design, provide useful information that can assist healthcare practitioners in clinical decision making.

Results

Search execution and application of the inclusion/exclusion criteria identified 33 studies, including 15 RCTs, 1 case–control study, and 17 case series studies. Studies meeting inclusion were broadly clustered into four musculoskeletal pain conditions based on underlying pathophysiology and/or anatomical pain location. These included 17 studies on tendinopathies, 8 studies on arthritic and degenerative conditions, 7 studies on spinal and pelvic pain, and 1 study on myofascial pain. MCID criteria were assessed where applicable.

In the rating of RCTs with the PEDro tool, one item was eliminated in the evaluation of two studies. In the study by Topol et al, item seven was eliminated because the sole outcome measure was a patient-administered psychometric instrument. A summary of each reviewed study is shown in Table 2. Except where otherwise stated, all studies utilizing a local anesthesia injection control used an identical agent and concentration contained in the dextrose injection.

Tendinopathies. The most robust data supporting the efficacy of prolotherapy for musculoskeletal conditions, compared to control injections, are for chronic, painful overuse tendon conditions. Independent of location, tendinopathies from repetitive motion, and overuse injury share markedly similar characteristics. Cases of tendinopathies in the Achilles tendon, common elbow extensor, patellar tendon, and patellar tendon possess similar histological, sonographic, and clinical features believed to represent an underlying noninflammatory painful degenerative pathophysiology. Histopathology of tendon biopsies in patients undergoing surgery for painful tendinopathy has revealed collagen separation, thin, frayed, and fragile tendon fibrils with lengthwise separation from other fibrils, disruption in cross section, and increase in tenocytes with myofibroblastic differentiation (tendon repair cells), proteoglycan ground substance, and neovascularization.

Consensus is growing regarding the efficacy of dextrose prolotherapy as an alternative to surgery for patients with chronic tendinopathy who have persistent pain despite appropriate rehabilitative exercise. The efficacy of dextrose injections in tendinopathy is believed to involve the initiation of a healing response secondary to cell membrane perturbation that follows a significant change in osmotic pressure between the extracellular matrix and tendon fibroblasts. Granulocytes and platelets gravitate to the inflammatory cytokines and chemotactic factors that are released from the cell membrane, which in turn release prohealing growth factors.

Reviewed studies. Osgood–Schlatter disease. Several trials enrolled patients with athletic injury resulting in tendinopathy unresponsive to conservative treatment. In one double-blinded study, young athletes aged 9–17 years with Osgood–Schlatter disease were randomized to dextrose injection, control injection, or to a noninjection (supervised exercise) group. Dextrose prolotherapy patients had substantially greater pain reduction during sport activity than either group at follow-up, with many pain-free during sport involvement. At one year, 84% of the dextrose-treated knees were pain free compared to 46% of the lidocaine-treated knees.

Temporal mandibular joint syndrome. Few studies have examined the effectiveness of prolotherapy for the treatment of temporal mandibular joint (TMJ) syndrome. One RCT found a significant functional improvement in TMJ patients who underwent dextrose prolotherapy compared to patients in the control group who only received injections of local anesthetic. Pain reduction, however, did not reach significance. Another RCT compared patients treated with dextrose prolotherapy and patients given a placebo. For both groups, masticatory efficiency increased, and general pain complaints and joint sounds decreased significantly. There was no significant difference in VAS scores between groups. However, the measurements of the maximum interincisal opening among the treatment group significantly decreased. One single case design study in which patients with TMJ were treated with injections of dextrose demonstrated decreased pain, increased quality of life as measured by the VAS, and absence of further dislocation or subluxation for more than six months.

Achilles tendinopathy. Four studies of Achilles tendinosis were evaluated. Yelland et al designed a treatment comparison study of eccentric loading exercise versus dextrose injection treatment versus combined exercise and injection to determine the best treatment for Achilles tendinosis. The VISA-A questionnaire (a valid and reliable index of the clinical severity of Achilles tendonopathy that measures the domains of pain, stiffness, function in daily living, and sporting activity) was used in this study. At 12 months, reduction in stiffness and limitation in activity was seen in 73% of the exercise only group, 79% of the injection only group, and 86% of the group treated with a combination of eccentric loading and dextrose injection. However, it is interesting to note that positive results were obtained fastest with prolotherapy alone.

In another study, Maxwell et al injected a dextrose solution into abnormal areas in the tendon and intrasubstance par-

Dextrose prolotherapy for chronic musculoskeletal pain

At 6 weeks and 12 months - Increases were significantly less for ELE than for combined treatment. Compared with ELE, reductions in stiffness and limitation of activity occurred earlier with prolotherapy and reductions in pain, stiffness and limitation of activity occurred earlier with combined treatment.

| Kim HS, et al. (2007) | South Korea | Double-blind RCT | Iliac crest pain syndrome | n = 44 | Active group: dextrose 20%, 1% lidocaine  
Control group: triamcinolone, lidocaine  
Weekly injection for 4 weeks | Outcome measure(s):  
• Mean change from baseline in VAS pain  
• Oswestry  
• Pressure threshold (algometer, kg/cm²) | 3 month follow-up  
Both groups improved in pain, disability and pressure threshold scores (P < 0.05)  
No significant difference between groups on any measure at any follow-up interval |
| Hooper et al. (2011) | Canada | Case series | Chronic cervical, thoracic or lumbar pain | n = 71 litigants (mean pain duration 2.1 years)  
n = 76 non-litigants (mean pain duration 6.3 years) | Active treatment: dextrose 20% injections into the facet capsules of the cervical, thoracic, lumbar spine  
Patients received weekly injections for up to 3 weeks, and 1 month later if needed | Outcome measure(s):  
• NDI  
• PSFS  
• RMDQ | At baseline, litigants compared to non-litigants:  
• Higher disability scores (P = 0.001)  
• More multiple regions affected  
• More cervical and thoracic regions affected (P < 0.0001)  
• Shorter mean symptom duration (P < 0.0001)  
1-year follow-up:  
Both litigants and non-litigants improved in all disability scales (P < 0.001).  
Percentage of litigants vs. non-litigants reporting improvement:  
• Impression of change scales for symptoms (91/92%) and function (90/90%)  
• Improved ability to work (76/75%)  
• Willingness to repeat treatment (91/93%)  
• Ability to decrease medication (82/81%)  
• Decreased need for other treatment (80/84%)  
Litigants showed greater improvement in treatment of the thoracic spine (P < 0.05) |
| Centeno et al. (2005) | United States | Case series | Neck pain | n = 6 | Treatment: dextrose 12.5% injections targeted instability sites including the spinous processes, lamina, and posterior elements | Outcome measure(s):  
• Mean changes from baseline in VAS pain scores  
• Radiographic findings | Pain scores, baseline and 1 month:  
5.75 and 3.83 (P = 0.04)  
Significant correlation between changes in pain scores and translation (rho = 0.88, P = 0.02).  
Significant correlation between changes in flexion and translation (rho = 0.94, P < 0.01) |
| Lee et al. (2009) | South Korea | Case series | Low back and pelvic pain | n = 22, mean duration 39.8 months | Treatment: Dextrose 25% injections every other week for 3 weeks | Outcome measure(s):  
• Mean changes from baseline in NRS pain scale  
• Oswestry | Mean (range) NRS scores: (P < 0.01)  
Baseline: 6 (4–8)  
10 weeks: 10 (0–3)  
Mean (SD) Oswestry scores (P < 0.01)  
Baseline: 34.1 (15.5)  
10 weeks: 12.6 (9.8)  
Mean duration of pain reduction ≥50% was 12.2 months |

(Continued)
tial tears (as visualized with ultrasound) in patients suffering from chronic Achilles strain. Using ultrasonographic imaging, significant reductions from baseline were found in the size of hypoechoic region in patients with midportion tendinosis, and in the size of intratendinous tear in patients with tendon thickness. In addition, pain decreased with treatment in 78% of the patients, and ultrasounds showed that the tendons became healthier as demonstrated by fewer discontinuities in the tendon and better organization of the fibers.\textsuperscript{64}

Ryan et al enrolled 99 patients with chronic Achilles tendon symptoms and objective evidence of Achilles degeneration by ultrasound who had failed all previous therapies. Treatment method involved injection inside the tendon with ultrasound guidance into areas of degeneration (hypochogeticity or tear) with 0.5 mL or less 25% dextrose in 1–3 spots at each treatment. At follow-up, improvement in pain with everyday living improved from 57% at a mean of 28 weeks into treatment to 81% at a mean of 14 months posttreatment. More change was seen by ultrasound at a mean of 28 weeks in the mid-Achilles tendinosis group with significant reductions in the size of hypoechoic regions, intratendinous tears, and neovascularization.\textsuperscript{65} Lyftogt also found an absence of pain in 78.5% of their small sample of patients with Achilles tendinopathy when treated with prolotherapy.\textsuperscript{66}

Lateral epicondylitis of the elbow. Three studies have demonstrated that lateral epicondylitis of the elbow is responsive to treatment with dextrose prolotherapy.\textsuperscript{67–69} Scarpone et al conducted a small double-blind RCT with adults with lateral epicondylitis. The treatment group was injected at 0, 1, and 3 months with 0.72% sodium morrhuate, 10.7% dextrose, 0.29% lidocaine, and 0.04% sensorcaine. The treatment group showed significant improvement in pain levels compared with patients given saline injection with the same number of needle punctures and volume (91% versus 33%). In addition, extension strength and grip strength was markedly improved in the treatment group as well.\textsuperscript{67}

Shin et al studied 84 patients with lateral epicondylitis who were treated with dextrose prolotherapy. The pain score was evaluated by using VAS before treatment and one and six months after the third treatment. Ultrasonography was performed on 49 patients who were suspicious of a tendinous tear. Dextrose prolotherapy decreased VAS from 6.79 to 2.95, which reached statistical significance.\textsuperscript{68} Park et al.\textsuperscript{69} achieved a significant reduction in pain with VAS from baseline patients with lateral epicondylitis as well with treatment of the lateral epicondyse with 15% dextrose. Evidence of tendon healing was observed via ultrasound imaging, manifesting as diffuse fibrillar patterns in previously anechoic lesions\textsuperscript{67,68} and areas of hypervascularity.\textsuperscript{69}

Patellar tendinopathy. A case series conducted by Ryan et al examined whether ultrasound-guided injection of hyperosmolar dextrose for treatment of patellar tendinopathy decreased pain scores and normalized the appearance of the patellar tendon on ultrasound. Findings revealed significant reductions in pain at rest and during activity, an overall downgrading of severity in intratendinous tearing
and neovascularity as evident with ultrasonography, and a significant correlation between the differences in pain and echotexture severity.76

Plantar fasciitis. Few studies have been conducted examining the effect of prolotherapy on chronic plantar fasciitis. However, Kim and Lee conducted a single-blinded, randomized, controlled study comparing autologous PRP versus dextrose prolotherapy treatments for chronic calcific plantar fasciitis. Patients in both treatment groups received two injections into the plantar fascia under ultrasound guidance at an interval of two weeks. The outcome measures included the pain, disability, and activity limitation subscales measured by means of the Foot Function Index. Each treatment seems to be effective for chronic calcific PF, expanding the treatment options for patients in whom conservative care has failed. Although PRP treatment resulted better initial improvement in function compared with dextrose prolotherapy treatment, at two- and six-month follow-ups, sustained improvement was comparable in both groups.71

Groin pain. Two uncontrolled trials in athletes with chronic groin pain from osteitis pubis and/or adductor tendinopathy were conducted by Topol et al.72,73 The treatment consisted of monthly injections of 12.5% dextrose with 0.5% lidocaine in abdominal and adductor attachments on the pubis. Therapy yielded substantial reductions in VAS pain and Nirschl Pain Phase Scale (NPPS), a 7-point measure of sports-related symptoms and level of participation, scores and an absence of pain at follow-up in 88.8% and 83.3% of patients, respectively.72 In the second study, Topol et al.73 treated elite rugby and soccer players experiencing chronic groin pain with similar results in pain reduction.

Shoulder joint pain. Dextrose prolotherapy has been shown to reduce pain and disability of traumatic and nontraumatic rotator cuff condition. A RCT conducted by Bertrand et al.74 revealed that treatment of moderate to severe rotator cuff tendinopathy due to injury with injections of hypertonic dextrose on painful entheses resulted in superior long-term pain improvement and patient satisfaction compared with blinded saline injection over painful entheses, with intermediate results for entheses injection with saline. In a retrospective case-control study, Lee et al.75 demonstrated dextrose prolotherapy improved in pain, disability, isometric strength, and shoulder active range of motion in patients with refractory chronic nontraumatic rotator cuff disease.

Conclusions regarding tendinopathies. Although there is a dearth of studies on treatment with prolotherapy for these two conditions, there is strong Level 1 evidence that dextrose prolotherapy results in substantially reduced pain levels and pain-free resumption of sport activities in Osgood–Schlatter disease69 and functional improvement and pain reduction in TMJ.60 Dextrose injections present a low-cost and safe treatment alternative with good long-term evidence for significant reduction of pain from pathology at either the insertion or midportion of the Achilles tendon, at rest and during tendon-loading activities. There is strong Level 4 evidence of statistically and clinically significant reduction in pain from baseline to follow-up in Achilles tendinosis,53,64 and specifically evidence of substantial and comparable pain reduction in patients with midportion or insertion site tendinopathy in Achilles tendinosis,76 and somewhat greater tendon healing in patients with midportion versus insertion site tendinopathy.65 There is strong Level 4 evidence of statistically and clinically significant reduction in pain from baseline to follow-up in dextrose prolotherapy treatments to lateral epicondylitis,67–69 overuse patellar tendinopathy,70 chronic groin pain,72,73 and traumatic and nontraumatic shoulder pains.74,75 Sonographic evidence of tendon repair and healing after dextrose prolotherapy treatments has been shown in Achilles tendinosis,64,65 lateral epicondylitis,68,69 and overuse patellar tendinopathy with a significant correlation between pain reduction and tendon healing in overuse patellar tendinopathy.70 Prolotherapy has also demonstrated a good response in patients with chronic plantar fasciitis reducing pain during rest and activity75; however, further studies including a control group are needed to validate these outcomes.

OA and degenerative conditions. OA is characterized by progressive breakdown of articular cartilage, proteoglycan degradation, and disruption of the collagen network resulting in joint destruction and loss of function.76 In addition to genetic and biochemical factors, several external factors have been associated with OA. These include sudden impact, direct trauma, overuse or repetitive motion injuries, avascular necrosis, corticosteroids, obesity, and ligamentous injury culminating in joint hypermobility and instability.77 Ligament damage resulting in weakness is an important factor in the development of OA as it prevents normal distribution of weight and increases stress on the articular surfaces of the joint causing cartilage injury and joint degeneration. Ligament laxity and joint capsule disruption increases joint hypermobility and also risk of articular cartilage injury due to loss in the stabilization of joint motion by the ligament structure.96–98

Experimental studies have shown the positive effect of hypertonic dextrose in promoting direct intracellular expression of growth factors in tenocytes and fibroblasts.83 Dextrose prolotherapy may also benefit those with knee OA through the stabilization of interarticular ligaments by its positive effect on joint mechanics to promote articular cartilage recovery and improvement in range of motion.83,84

Reviewed studies. Knee OA. A three-arm randomized controlled double-blinded study conducted by Rabago et al found significantly greater improvement in pain reduction, swelling, buckling episodes, and flexion range with dextrose compared with lidocaine injections or exercise. Furthermore, prolotherapy patients showed significantly greater improvement at 52 weeks than control patients.75 In a recently published analysis, Rabago et al.79 reported that most participants have continued to experience progressive improvement of knee pain, function, and stiffness scores at 2.5 years after the initiation of the study.
An RCT conducted by Reeves and Hassanein revealed that patients with knee laxity treated with dextrose injections experienced significant improvement in knee flexion range and anterior displacement difference (ADD), with 61.5% exhibiting an absence of laxity as compared with the control group. A long-term open-label continuation of this trial involving the patient subgroup with knee laxity found continuity of effect with significant improvements from baseline in pain during walking and stair use, flexion range, ADD, and a similar proportion of patients with an absence of laxity at follow up.

Dumais et al conducted a crossover study where participants were randomly assigned to receive exercise therapy for 32 weeks in combination with dextrose injections on weeks 0, 4, 8, and 12 or dextrose injections on weeks 20, 24, 28, and 32. Both groups showed significant reduction of knee OA symptoms as measured by WOMAC scores that were sustained at six-month follow-up.

Eslamian and Amouzandeh also demonstrated the long-term effects of dextrose prolotherapy in a single-arm prospective study. Significant therapeutic effects of prolotherapy with intraarticular dextrose injection in patients with moderate knee OA were achieved. Pain severity, as measured by WOMAC scores, was reduced at rest and during activity, and articular range of motion was increased. Improvements were still present at six-month follow-up.

In one RCT by Hashemi et al, the efficacy of dextrose versus ozone as a proliferant was compared in two groups of 40 patients suffering from mild to moderate knee OA. Both groups received intraarticular injections, and the treatment was performed three separate times at 10 days intervals. VAS and WOMAC scores at pretreatment and three months posttreatment were significantly improved for both groups, although were not statistically different between one other.

Finger and thumb OA. A randomized control trial of patients with thumb and finger joint OA conducted by Reeves and Hassanein found significantly greater improvement among dextrose versus lidocaine patients in pain with movement, flexion motion, and joint narrowing. However, the difference in movement pain was the most impressive, reaching statistical significance with 42% versus 15% improvement.

In a second randomized control trial of patients with thumb joint OA, Jahangiri et al demonstrated dextrose/lidocaine injections resulted in more favorable VAS scores and improved total function at six months compared to corticosteroid injections, which at one month were offered more pain relief than prolotherapy but without sustained benefit.

Conclusions regarding OA/degenerative conditions. There is strong Level 1 evidence that in patients with knee OA, dextrose prolotherapy results in significant sustained improvement, including reduction of pain and swelling, fewer buckling episodes, increased knee flexion range, increased lateral patellofemoral cartilage thickness, and decreased ADD and laxity. There is Level 1 evidence demonstrating that in patients with osteoarthritic finger and thumb joints, dextrose prolotherapy results in significant improvements in pain with movement, flexion range, and joint narrowing. There is Level 4 evidence of significant improvements in OA-related pain, stiffness, and function in patients with knee OA and significant improvements in pain during rest, walking, and stair use, flexion range, and ADD in OA patients with anterior cruciate ligament (ACL) laxity.

**Spinal and pelvic pain.** In approximately 90% of patients, low back pain is mechanical in nature, typically originating from overuse, straining, lifting, or bending that results in ligament sprains, muscle pulls, or disk herniation. The popular understanding of back pain is disk herniation as a frequent cause, but to a much greater extent, ligament injury forms the underlying basis. Ligaments hold the disk in place, and with ligament weakness, the disk is more likely to herniate.

The source of low back and buttock pain as related to the sacroiliac (SI) joint is present in as many as 15%–30% of back pain patients, and perhaps up to 40% in patients who have had a previous lumbar fusion. SI joint dysfunction may also produce pain similar to a herniated lumbar disk along the same sciatic nerve distribution. Low back pain patients who remain symptomatic despite tailored physiotherapy are believed to possess deficient ligament strength in the posterior elements of the SI joint, resulting in insufficient stability to permit effective muscle recruiting strategies. Experimental studies have found prolotherapy effective in stimulating the production of collagen fibers, thus strengthening ligaments.

Reviewed studies. Discogenic leg pain. Dextrose prolotherapy has been effective in treating patients with coccygodynia pain in both case series studies and RCTs. In a prospective case series with patients experiencing advanced degenerative discogenic leg pain who had failed other treatment, Miller et al. found that 43% showed sustained improvement with an overall reduction in NRS pain of 71%. In a case series study, Khan et al. found that patients with coccygodynia pain experienced a substantial reduction in pain with mean VAS pain scores dropping from 8.5 at baseline to 2.5 after two dextrose injections spaced 15 days apart. Two RCTs compared the effects of dextrose and steroid injections for low back pain. In patients with SI joint pain, Kim et al. found a significantly greater cumulative incidence of pain reduction in dextrose versus steroid-injected patients. In contrast, a trial conducted by Kim et al., with brief follow-up in patients with iliac crest pain syndrome found no difference between dextrose and triamcinolone in VAS pain and disability scores; both groups showed significant pain decrease from baseline.

Hooper et al compared treatment outcomes in patients with cervical, thoracic, or lumbar pain who were involved or not involved in pain-related litigation. Both groups showed significant improvement in pain and disability with dextrose prolotherapy. Using radiographical imaging and VAS pain scores...
one month following dextrose injections in six patients with traumatic cervical instability and neck pain, Cenento et al.91 found that patients experienced significant pain reduction and reduction in cervical flexion and extension translation, with a correlation between differences in pain score and translation reduction. Lee et al.92 performed a prospective uncontrolled trial in patients with SI pain and found a mean duration of pain reduction ≥50% of 12.2 months in patients who received dextrose injections into their SI joints.

Conclusions regarding spinal and pelvic pain. There is Level 1 evidence that dextrose prolotherapy results in significantly greater long-term pain reduction than corticosteroid injection in patients with SI joint pain,88 and Level 2 evidence of comparable short-term pain reduction versus corticosteroid injection in patients with SI pain.89 There is strong Level 4 evidence of significant and comparable improvement in pain and disability between patients with chronic cervical, thoracic, or lumbar pain actively involved versus not involved in litigation.90 There is Level 4 evidence of significant pain reduction and association between changes in pain level and radiographical findings in patients with post-motor vehicle accident neck pain and disability,91 significant reduction in pain and disability in patients with low back and pelvic pain,92 and significant pain reduction in patients with coccygodynia.97

Myofascial pain syndrome. The theoretical basis for dextrose prolotherapy in myofascial pain syndrome (MPS) suggests that since MPS is a state of deficient energy metabolism, dextrose injection into myofascial trigger points may stimulate energy production to relieve the associated pain syndrome.93

Reviewed Studies. In an RCT, patients received injections of dextrose 5%, saline solution, or lidocaine 0.5%. At 7 days postinjection, dextrose-treated patients were improved from baseline in pain (VAS) and pressure threshold tolerance (algometer; kg/cm²) (P < 0.05); saline and lidocaine patients did not show improvement from baseline on either measure.93

Conclusions regarding MPS. Improvement in pain following dextrose prolotherapy comes from Level 2 evidence.93

Discussion
This systematic review identified 33 studies evaluating the efficacy of dextrose prolotherapy for chronic musculoskeletal pain. Of the studies reviewed, 14 were RCTs, 1 was a case–control study, and 18 were case series. Fifteen of the 33 studies used subjective VAS/NRS measures only. The remaining 18 studies combined subjective measures with objective measures, including imaging/biomechanical and/or psychometric measures. Collectively, these studies showed relative consistency in treatment outcome – noteworthy considering the overall heterogeneity. Sixteen of the 18 studies reported positive consistency between subjective and objective outcomes; one study found positive subjective and objective outcomes at short-term follow-up and positive objective but not subjective outcomes at long-term follow-up; and one study reported positive outcomes on objective measures only. Both studies analyzing the association between subjective and objective outcomes reported significant correlational data. In aggregate, the studies showed wide variation in patient characteristics, study design, and outcome measurements. Grouping the studies into four musculoskeletal pain conditions based on underlying pathophysiology and/or anatomical pain location provided substantially greater homogeneity within pain groups.

The quality of evidence for the RCTs was very high with those evaluated with the PEDro tool producing scores ≥8. RCT results found that patients randomized to dextrose showed significantly greater improvement in Osgood–Schlatter disease,78 rotator cuff injury,73 knee OA,77,78 osteoarthritic finger and thumb joints,84 and MPS93 than patients randomized to anesthetic injection. Dextrose-treated patients also showed significantly greater improvement compared with patients randomized to saline injections in knee OA82 and MPS93 and with patients randomized to treatment-as-usual in Osgood–Schlatter disease58 and knee OA.92 In an RCT involving patients with TMJ, patients assigned to dextrose injection showed comparable subjective improvement to the anesthetic control group but significantly greater improvement on biomechanical measures.89

In RCTs comparing dextrose to corticosteroid injection, Kim et al.88 found comparable pain reduction when injected into the SI joint, while Kim et al.89 found superior pain reduction with dextrose. This outcome discrepancy is likely explained by the patient follow-up duration of 3 versus 15 months in Kim et al.88 versus Kim et al.89, respectively. A recent meta-analysis concluded that corticosteroid injection for chronic musculoskeletal pain is associated with definite short-term (<8 weeks) benefits and worse intermediate and long-term outcomes compared with other treatment options.108 Two aspects of the Kim et al.89 study warrant additional mention: the very high baseline patient pain levels [mean ± SD VAS pain score 8.04 ± 1.17 (dextrose group) and 8.13 ± 1.28 (steroid group) (NS)], and the superiority of dextrose injection in short-term pain relief compared with a standard therapy for moderate–severe musculoskeletal pain.

To replicate the experimental group protocol, eight RCTs utilized local anesthesia injection, four utilized saline, and one study utilized lidocaine/saline as a placebo control condition (other than dextrose injection). While in the narrow sense, these control conditions differ from conventional placebo in that they are not completely inert, these conditions are difficult to achieve outside of pharmaceutical trials, and this protocol fulfills a goal of placebo-control in blinding patients and investigators to treatment assignment.109

Prolotherapy for musculoskeletal pain has been in clinical use for decades but only recently has the methodological quality of the published research evolved beyond the minimum level necessary for consideration in the practice of evidence-based medicine.110,111 The Grading of Recommendations Assessment, Development and Evaluation (GRADE)
is a widely accepted and utilized criterion for evaluating the
evidence quality in treatment recommendations. The types of
evidence are hierarchically ranked based on study design, with
RCTs at the highest level of clinical study and uncontrolled
studies at a much lower level.112,113 This ranking reflects the
greater ability of RCTs to minimize the effect of bias and
confounding factors on outcome, such that stricter experi-
mental control can produce observed treatment effects that
more closely approximate the true treatment effect, and with
it a more valid inference of causality.114

Uncontrolled studies possess a greater capacity for dis-
torted outcome reporting than RCTs given the inability to
experimentally control many forms of bias and confounding
factors.114 However, the GRADE system also recognizes that
uncontrolled studies with rigorous methodology, a large treat-
ment effect, consistent evidence from multiple studies, and
to the extent possible the ruling out of alternate explanations
for positive findings possess strengths that increase the study
grade and level of evidence.112,113 It bears mention that several
therapies, such as insulin for diabetes and defibrillation for
ventricular defibrillation, have been accepted as the standard
care without RCT confirmation of the results from less rig-
ously designed studies.115,116

The GRADE system also gives consideration to the bal-
ance between the health benefits and harms of a therapy.112
The reviewed studies were primarily comprised of patients
with moderate to severe levels of pain and functional impair-
ment refractory to established therapies. When outcome con-
 sistency, durability of effect, safety, lack of other treatment
options, short of surgery or invasive interventional procedures,
and low cost are considered, dextrose prolotherapy for chronic
musculoskeletal pain surpasses this threshold.

Particular strong points in many of the uncontrolled
studies serve to elevate their quality of evidence. For example,
many studies combined objective measures, such as sono-
graphic, radiographical, or biomechanical data with subjec-
tive assessment. Objective measurements were utilized and
revealed positive outcomes in several uncontrolled studies,
including Achilles tendinopathy,64,65 lateral epicondylitis of
the elbow,67,69 knee OA,79,80,82 finger and thumb OA,84,85
chronic SI/iliolumbar pain,89,90 and myofacial pain.91 The
positive findings in tendinopathies, knee OA, SI pain, and
iliac crest pain were confirmed by the results of RCTs. The
rigorous study design, data reporting, and clinical generaliz-
ability found in many of these studies were reflected in their
D&B score. Interestingly, while many uncontrolled studies
used highly stringent inclusion/exclusion criteria and exten-
sive diagnostic screening for highly specific patient enroll-
ment, others included patients with nonspecific pain, more
closely mirroring real-world clinical practice.

Many studies assessed treatment response with VAS
or NRS patient self-rating. The reliability and validity of
these measures has been questioned based on the subjective
nature of pain, and wide variations in patient reporting of
baseline pain scores and in applying self-rating to their own
pain experience.117 However, no objective pain measurement
exists, and VAS/NRS remains the clinical standard in assess-
ing baseline pain level and treatment response.53 Both scales
are also widely used in pharmacotherapy efficacy studies; for
instance, the pivotal trials of two recently approved opioid
formulations for chronic moderate–severe pain, tapentadol
ER,118,119 and hydromorphone ER120,121 utilized pain NRS
in the assessment of primary study objectives.

Dextrose prolotherapy is a safe therapy, and few adverse
events were reported in the reviewed studies. No serious or
protracted complications were observed, including nerve dam-
age, pneumothorax, and infection. Although adverse events
have the potential for greater severity in the treatment of spi-
nal and intraarticular structures, injection by an experienced
prolotherapist can help mitigate this risk.52 Dextrose itself is
extremely safe, even with intravenous administration. In a
1998 Food and Drug Administration document, no adverse
events had been reported to Abbott Labs for 25% intravenous
dextrose solution in 60 years.122,123

Study limitations. The findings in this review may be
influenced by publication bias, where studies reporting nega-
tive findings are not prepared, submitted, or accepted for
publication. Potentially present is reference bias, where the
outcomes of references obtained from secondary sources, such
as review articles, meta-analyses, and practice guidelines, may
be biased in the direction desired by the authors of the review
article or practice guideline. It is unlikely that this review pos-
sesses reference bias, in that all reviewed studies were obtained
from database searches.

Summary
This systematic review evaluated 32 studies on dextrose pro-
lotherapy for chronic musculoskeletal pain. Based on the level
of evidence, quality of evidence, and factors directly and indi-
rectly related to evidence quality including the consistency of
significant reductions in pain and impairment found within
pain groups, between pain groups, across uncontrolled stud-
ies between pain groups and conditions, between uncon-
trolled studies and RCTs in multiple specific pain conditions,
between VAS/NRS outcomes and psychometric, biomechani-
cal, and imaging outcomes within studies, the consistent sta-
tistically significant improvement in pain and functioning
among patients randomized to dextrose versus control groups,
the consistent achievement of clinically meaningful reduc-
tions in pain level among studies using VAS/NRS outcomes,
and the absence of reported side effects other than transient
injection site irritation, the following conclusions are made:
dextrose prolotherapy is supported in the treatment of tendi-
nopathies in patients who fail conservative therapies; dextrose
prolotherapy is supported in the treatment of OA of the knee
and finger joints in patients who do not respond to conserva-
tive therapies; dextrose prolotherapy is supported in the treat-
ment of spinal and pelvic pain in patients who fail to respond
